EXECUTIVE SUMMARY

This report is the summary of all entomological data collected in 2017 by AIRS Mali.

Lab training to improve the quality of molecular results was conducted for staff from Laboratoire de Biologie Moléculaire Appliquée (LBMA) from June 11-23, 2017. Later, a regional lab training was carried out for two weeks in Cotonou with two participants from LBMA. A follow up of these two trainings was performed in Mali by the University of Notre Dame from December 4-8, 2017 and indicated that good progress had been made in terms of quality of the data provided by molecular analyses, particularly for molecular species identification and sporozoite Enzyme Linked Immuno Sorbent Assay (ELISA).

World Health Organization (WHO) tube tests performed under the framework of the national insecticide resistance monitoring plan revealed full susceptibility to pirimiphos-methyl 0.25% in all sites. Several sites showed resistance or possible resistance to bendiocarb. Resistance to permethrin 0.75%, alphacypermethrin 0.05%, and deltamethrin 0.05% was recorded in all 15 surveyed sites. The intensity of resistance was generally higher to permethrin than deltamethrin. The intensity of resistance to these two pyrethroids is strong—there were survivors in all sites at 10 times the diagnostic dosage. Data showed mortality rates in the four IRS sites with clothianidin 13.2 mg/paper of less than or equal to 90 percent after four days and greater than or equal to 98 percent after 6 days, but further optimization of the protocol may be needed. Since the protocol used to test clothianidin is not yet standardized and validated by the WHO, the mortality rates of less than 98 percent that we obtained cannot be interpreted as signs of resistance.

In September (one month after spraying), mortality rates with WHO cone bioassays, using An. gambiae Kisumu, were still at 100 percent, regardless of the type of wall. The fumigant air-borne effect of the sprayed insecticide was between 77 and 100 percent depending on the wall substrate. At the end of bioassays, residual duration was three months for mud, and longer for painted substrates such as painted cement, painted mud, and a combination of painted mud and cement. The fumigant effect lasted longer than expected with particularly high mortality rates occurring two months after spraying.

Morphological identification of mosquitoes collected from Human Landing Catch (HLC) and Pyrethrum Spray Catch (PSC) indicated that An. gambiae s.l. was the predominant malaria vector (96 percent of the collected vectors) followed by An. pharoensis, An. rufipes, An. ziemanni and An. funestus. An. coluzzii was the most common species of the An. gambiae s.l. complex. Overall, from PSC conducted before IRS (June-July), there was a mean of 6.2 An. gambiae s.l. per house in Mopti Region against 1.8 An. gambiae s.l. per house after IRS (August-December). In unsprayed former IRS sites, Koulikoro and Barouéli, the mean indoor vector density was 2.1 An. gambiae s.l. per house/day in June-July and 5.9 in August-December.

In the Mopti Region, before IRS, the average human biting rate (HBR) was 1.4 b/h/n in Djénné, 1.1 b/h/n in Mopti District, 2.9 b/h/n in Bandiagara and 0.5 b/h/n in Bankass. Post-IRS, the mean HBR ranged from 0.5 b/h/n in Bankass to 7.5 b/h/n in Mopti District. Biting behavior was more pronounced late at night and was similar outdoors (2.9 b/h/n) and indoors (2.4 b/h/n) after IRS. In Koulikoro and Barouéli (former IRS sites), mean biting rates for August to September 2017 were particularly high at 106.3 b/h/n and 13.4 b/h/n, respectively. In Kati, a control site that was not sprayed in either 2016 or 2017, the mean biting rate was 80.5 b/h/n from August to September 2017. Between August and September 2016 and the same period in 2017, there was a 4.9 fold increase in biting rate in Koulikoro (former IRS site) compared to a 1.7 fold increase in Kati (the paired control). Furthermore, after combining the post-IRS data, the mean HBR in August to December was 2.7 b/h/n

\[1\text{b/h/n} = \text{bites per human per night}\]
in IRS sites, 28.7 b/h/n in former IRS sites and 36.5 b/h/n in Kati, a control site. In former IRS sites, from August to December, infection of vectors was 0.8 percent (95% CI: 0.2-1.5) in 2017 as opposed to 1.3 percent in 2016 (95% CI: 0.2-2.5) in 2016; p=0.42. The entomological inoculation rate was 7.05 ib/h/5 months\(^2\) for these sites in 2016 while it was 15.37 ib/h/5months in 2017, which equates to a two-fold increase after IRS withdrawal. In Kati, the control site, the EIR was 18.6 ib/h/5 months in 2016 while it was 6.21 ib/h/5months in 2017. Furthermore, in IRS sites, the EIR ranged from 1.7 ib/h/5 months in Bankass to 12.2 ib/h/5 months in Mopti. Overall, relocation of IRS may have contributed to an increase in the key indicators of malaria transmission, particularly human biting rates.

\(^2\) ib/h/5 months = infective bites per human over 5 months
In 2008, malaria vector control by indoor residual spraying started in Mali with financial support from the President’s Malaria Initiative (PMI). At that time, a pyrethroid insecticide (lambdacyhalothrin) was used in Bla and Koulikoro districts, with the addition of Baroueli district in 2011. Given the large expansion of vector resistance to pyrethroids, lambdacyhalothrin was replaced by bendiocarb (carbamate) for IRS in 2012. However, the short residual duration of bendiocarb on sprayed walls led the National Malaria Control Program (NMCP) and its partners to spray Actellic 300CS (organophosphate) starting in 2014. With the support of the UNITAID-funded project NGenIRS, the 2016 campaign was carried out in Fana, in addition to the two districts (Koulikoro and Baroueli) covered by the PMI funding.

The Malaria Indicator Survey conducted in 2015 revealed that the incidence of malaria in the Mopti region was twice that of the national average. On the basis of these data, the NMCP of Mali in collaboration with PMI, decided to relocate IRS operations to Mopti region in 2017. IRS started at the end of July 2017, being timed to provide maximum impact during the peak malaria transmission period.

The 2017 campaign started on July 24, and was implemented in four districts, namely Djenne, Mopti, Bandiagara, and Bankass. Entomological monitoring began in June in seven sites—four IRS sites in Mopti region, two sites where IRS was withdrawn in Koulikoro and Ségou regions, and one unsprayed control site in Koulikoro region. In this report, we present data collected during IRS entomological monitoring carried out from June to December 2017 and nationwide vector resistance surveys.

Specific aims (covered in this final report) were to determine:

- Vector species composition
- Vector indoor resting densities
- Vector biting rates, times and location (indoor or outdoor)
- Sporozoite index (SI) and Entomological Inoculation Rate (EIR)
- Vector blood meal origin
- Quality of spraying and insecticide decay rate
- Susceptibility levels of An. gambiae s.l. to four classes of insecticides used in public health and to new vector control products (clothianidin and chlorfenapyr), resistance intensity and frequency of resistance mechanisms.
2. METHODOLOGY

2.1 STUDY AREA

2.1.1 IRS ENTOMOLOGICAL SURVEILLANCE SITES

In 2017, AIRS Mali collected data on key entomological indicators (all PMI basic and most advanced entomological indicators) from surveillance sites in the Mopti region as well as some sites in Koulikoro and Segou from which IRS was withdrawn (Table 1, Figure 1). Monthly surveillance was conducted in seven sentinel sites, four in Mopti and three in Koulikoro/Segou. All four sites in Mopti region are located in the IRS-targeted districts. There were no unsprayed control sites monitored in this area as there were no suitable, neighboring areas due to security concerns (i.e. all ‘secure’ sites were sprayed). Entomological surveillance was also conducted in Tienfala (Koulikoro) and Diaka Were (Baroueli), where IRS was conducted annually from 2013 to 2016, to monitor for signs of increased sporozoite rates, indoor resting densities, and biting rates.

2.1.2 Nationwide Sites For Insecticide Resistance Mapping

There were 15 resistance monitoring sites nationwide, the majority of which have been used for several years. The 15 sites include the 4 IRS target sites mentioned above and 11 other sentinel sites selected for various reasons shown in Table 2. The nationwide insecticide resistance survey was previously implemented in 2012, 2014, 2015 and 2016. Figure 2 shows the geographical position of each of the 15 sites.

Figure 2: Insecticide Resistance Surveillance Sites and Boundaries of the Eight Regions of Mali
2.2 **Human Landing Catch**

To determine human biting rates for the main malaria vector (An. gambiae s.l.), human landing catches (HLC) were conducted for two consecutive nights each month from 06:00 pm to 06:00 am in four randomly selected houses of each site. The same houses were used each month throughout the collection period (June-December 2017). During each night of HLC, two collectors each equipped with a mouth aspirator and a torch (Figure 3) sat in each house, one indoors and the second outdoors. The indoor collector was positioned in the living room of the house while the outdoor collector was located within 2m of the house. The indoor/outdoor collectors were rotated every hour to compensate for variation in their attractiveness. The following morning, mosquito identification was carried out using the Gillies & de Meillon (1968) key.

![Figure 3: Indoor Landing Catch](image)

2.3 **Pyrethrum Spray Catch**

Spritex aerosol containing tetramethrin 0.3% and permethrin 0.03% was used to perform pyrethrum spray catch (PSC) in 20 houses per site to sample indoor resting mosquitoes. Ten houses per day were visited during two consecutive days per month from 7:00 a.m. to 12:00 p.m. The surveyed houses were the same from June to December 2017. Before the start of PSC, all people, animals and food were removed from the houses. All the openings present in each house were blocked. White sheets were laid on the entire floor and the remaining furniture. Thereafter, a collector sprayed the houses (Figure 4). After spraying, the door was closed for 10-15 minutes. The collectors removed the canvas from the houses and then collected mosquitoes that were fallen. Mosquitoes were put in labeled petri dishes. They were morphologically identified as Anopheles and culicines and separated by sex. Abdominal status (unfed, fed, half gravid and gravid) of all female Anopheles was determined. Females of Anopheles gambiae s.l. were preserved in 1.5 ml labeled Eppendorf tubes containing 70% ethanol for further processing in a molecular lab.

![Figure 4: House Spraying with Aerosol](image)

2.4 **Wall Cone Bioassay and Fumigant Tests**

To determine the quality of spraying on walls and the decay rate of the insecticide, bioassays were conducted one to two days after IRS followed by a monthly monitoring, using a susceptible colony of An. gambiae s.s. Kisumu strain that is reared in Bamako at the AIRS insectary. Mosquitoes were transported monthly by road in cooler boxes for bioassay testing. Cone bioassays were conducted in the four IRS districts (Mopti, Bandiagara, Bankass, and Djenne) according to WHO protocols.

In total, cone bioassays were conducted in 20 structures, which is equal to 5 houses per district. In each sprayed house, Kisumu strain were exposed on a wall at varying heights 0.5 m, 1.0 m, 1.5 m and 2.0m from the floor. A control cone was set on a plywood board outside of each sprayed house in a shaded area near to the house.
Fumigant bioassays were also carried out in each tested house to determine the contribution of airborne effects to overall mortality in cone bioassays. A small wire cage measuring 15cm by 10cm covered with untreated polyester netting material was placed approximately 10cm from a sprayed wall and about 1 meter above the floor. Exposure time was 30 minutes, with mortality subsequently recorded 24 hours later. A parallel control test was performed by exposing the same number of mosquitoes in a wire cage in a neighboring untreated house.

### 2.5 Mosquito Larvae Collections and Rearing

From June to September 2017, all 15 insecticide resistance monitoring sites were surveyed by the AIRS Mali team using larval collections. Larvae and pupae of *An. gambiae* s.l. were collected from sites using dippers (Figure 5). Larvae and pupae were sorted by genus and brought back to the field rearing room until the adult stage.

### 2.6 WHO Susceptibility Tube Tests

Four batches of 20 to 25 non-blood-fed females *Anopheles*, aged two to five days were used for the susceptibility tube tests (Figure 6) according to the World Health Organization protocol (WHO, 2016). These tests were performed with permethrin 0.75%, alphacypermethrin 0.05%, deltamethrin 0.05%, bendiocarb 0.1% and pirimiphos-methyl 0.25%. Knock-down was recorded in time intervals (10, 15, 20, 30, 40, 50 and 60 minutes). After 60 minutes of exposure, the mosquitoes were transferred into the observation tubes and fed with a 10% sugar solution. Mortality was recorded at the 24-hour mark.

Furthermore, susceptibility tube tests were performed in the four IRS sites using filter papers impregnated with clothianidin, 13.2 mg ai per paper. Papers treated with distilled water were used as negative control. Mortality rates were recorded each day for seven days after the tests. Sumitomo recommends using seven days as the time for recording total mortality.

Dead and live mosquitoes were stored in 1.5 ml Eppendorf tubes containing silica gel for future molecular analyses (polymerase chain reaction (PCR) species, \textit{kdr} 1014F, \textit{kdr} 1014S and \textit{Ace1}R).
2.7 BOTTLE BIOASSAYS

Insecticide resistance intensity was assessed by the United States’ Center for Disease Control and Prevention (CDC) bottle assay which involved coating 250ml bottles with varying concentrations of permethrin or deltamethrin (1x, 2x, 5x, and 10x of the diagnostic concentration).

Chlorfenapyr Technical Grade of the Active Ingredient was received in October and bottle bioassays were conducted at different dosages: 12.5 µg/ml, 25 µg/ml, 50 µg/ml, 100 µg/ml, 200 µg/ml.

The bottles were air-dried overnight and two- to five-day-old mosquitoes were exposed in the treated bottles with mortality monitored every 15 minutes for one hour (Figure 7). The diagnostic time was 30 minutes. A bottle coated with acetone was used as a control.

2.8 MOLECULAR CHARACTERIZATION OF MOSQUITOES

All molecular analysis was conducted by LBMA, Bamako. Female Anopheles were analyzed by PCR for species identification according to the protocol described by Santolamazza et al., 2008. This method allows both identification of Anopheles species and molecular forms discrimination. The L1014F and L1014S kdr mutations were respectively identified according to the protocol of Huynh et al., (2007). The detection of the Ace1R mutation was done following the protocol described by Weill et al. (2004).

Adult females collected by HLC were used for circumsporozoite protein (CSP) enzyme-linked immunosorbent assays (ELISA) using the protocol of Wirtz et al. (1987). Blood meal origin was performed according to the PCR protocol of Kent et al. (2005).

2.9 DATA ANALYSIS

For PSC, the mean density of An. gambiae s.l. was determined in the following way:

- Total number of vectors collected by species / Total number of houses surveyed.

The HBR was determined from HLC using the formula:

- Total number of vectors collected / Total number of human nights.

A Chi-square test was used to compare the indoor and the outdoor biting rates.

For the susceptibility tests, the resistance status of each site was determined according to the WHO criteria (2013). When the mortality rate is below 90 percent, the mosquito population is considered resistant. When the mortality rate is between 90 and 97 percent, there is a suspicion of resistance. If the mortality rate is above 98 percent, the mosquito population is considered susceptible.

The sporozoite index was calculated by dividing the total number of infected vectors by the total number of vectors tested with ELISA and multiplying by 100.

A Z-test for difference in proportions was used to compare the sporozoite index and mortality rate between two populations.
3. RESULTS

3.1 VECTOR SPECIES COMPOSITION

Five different Anopheles species were encountered: An. gambiae s.l., An. pharoensis, An. rufipes, An. funestus s.l., and An. ziemanni. The most predominant vector was An. gambiae s.l. which accounted for more than 96 percent of the collected Anopheles mosquitoes irrespective of the sampling method (Table 3). After combining data from the two collection methods (HLC and PSC), only 371 An. pharoensis, nine An. rufipes, four An. ziemanni and three An. funestus were captured out of 13,935 Anopheles. The total number of each mosquito species collected is presented in Table 3.

Mosquitoes collected from the two sampling methods (HLC and PSC) were used for molecular species identification. A maximum of 35 specimens of An. gambiae s.l. captured from each site were then analyzed by PCR on a monthly basis. The results revealed, out of the 686 specimens of An. gambiae s.l. that were tested, 92.7 percent were An. coluzzii (n=636), 5 percent were An. gambiae (n=34), 0.9 percent were An. arabiensis (n=6), 0.1 percent were hybrid coluzzii x gambiae (n=1), and 1.3 percent (n=9) did not amplify (Figure 8). More details are in Annex A, Table A1. The proportion of each species for each site is presented in Figures 9 through 12.

3.2 Indoor Vector Resting Density

Over the study period, the indoor vector density in Djénné, Mopti, Bandiagara, and Bankass (IRS sites) was between 0.1-19.3, 1.5-11, 0.2-10.7 and 0-3.6 An. gambiae s.l. per house per day, respectively. The cumulative data in IRS sites revealed a post-IRS vector density of 1.8 An. gambiae s.l. per house per day, while the density was 6.2 An. gambiae s.l. per house per day before IRS. Overall, indoor resting densities decreased as expected after the spraying except in Mopti in October and Bankass in September. In IRS sites, the month during which the highest indoor vector density was recorded varied by district—July in Djénné and Bandiagara, August in Bankass, and October in Mopti (Table 4).

In unsprayed former IRS sites, the mean indoor vector density was between 0.6-12.3 and 0.1-13.5 An. gambiae s.l. per house per day in Koulikoro and Barouéli, respectively. In Kati, where spraying has never occurred, the indoor vector density ranged from 0.3 to 13.9 An. gambiae s.l. per house per day. In unsprayed former IRS sites and in the control site, the peak in indoor vector density was obtained in August/September (Table 4).

3.3 Human Biting Rate in An. gambiae s.l., Seasonality

Overall, the peak in An. gambiae s.l. biting rate was obtained in August and September at all sites. In the Mopti Region, before IRS, the average An. gambiae s.l. HBR was 1.4 b/h/n in Djenné, 1.1 b/h/n in Mopti district, 2.9 b/h/n in Bandiagara, and 0.5 b/h/n in Bankass (Table 5). In the former IRS sites, the mean An. gambiae s.l. HBR during the same period was zero in Barouéli while it was 15.2 b/h/n in Koulikoro. The highest mean HBR (20.2 b/h/n) was obtained in Kati, a control site that has never been sprayed.

Post-IRS, in the Mopti Region (sprayed sites), the mean An. gambiae s.l. HBR ranged from 0.5 b/h/n in Bankass to 7.5 b/h/n in Mopti District. The mean An. gambiae s.l. HBRs for August and September 2017 in Koulikoro and Barouéli (former IRS sites) were particularly high at 106.3 b/h/n and 13.4 b/h/n, respectively, as compared to the same period of 2016 when it was 21.5 b/h/n and 0 b/h/n, respectively (Figure 13). The tendency was the same in Kati, a control site that wasn’t sprayed in either 2016 or 2017, with a mean HBR of 80.5 b/h/n in August through September 2017 compared with 46.2 b/h/n in 2016. Between August-September 2017, there was a 4.9 fold increase in HBR in Koulikoro compared with the same period in 2016, while the increase in Kati (the paired control) was to a lower magnitude (1.7 fold). Overall, after combining the 2017 data, the mean HBR was 2.7 b/h/n in IRS sites, 28.7 b/h/n in former IRS sites, and 36.5 b/h/n in Kati, a control site. More details are given in Annex B, Table B1.

b/h/n: bite per human per night
3.4 Biting Times of An. gambiae s.l.

Figures 14 through 18 display the same tendency in terms of biting times for An. gambiae s.l. in IRS, former IRS, and control sites. The biting behavior was more pronounced late at night indoors and outdoors, with little biting before 10 at night. The biting times are not presented for Bandiagara and Bankass given fewer than 160 An. gambiae s.l. were collected. More details are available in Annex C, Tables C1 and C2.

3.5 BITING LOCATION OF AN. GAMBAE S.L.

The frequency of indoor and outdoor biting rates of *An. gambiae* s.l. in each site is shown in Table 6 (more details are provided in Annex D, Tables D1 and D2). Prior to IRS, *An. gambiae* s.l. biting rates were similar indoors and outdoors at all sites except for Djénné (IRS site 1) and Bandiagara (IRS site 3) where there was more biting indoors. As pre-IRS sampling was only done for two months, no valid conclusion can be drawn regarding the differences observed. Post-IRS, biting behavior in *An. gambiae* s.l. was variable according to each IRS site (Djénné, Mopti, Bandiagara, and Bankass), but after combining the data, biting rates were similar indoors and outdoors in IRS sites. There were also similar indoor and outdoor biting rates in former IRS sites and the control site (Table 6).

3.6 Sporozoite Index

In each assessment site, the proportion of infected mosquitoes was evaluated on a monthly basis (Table 7). The details on the number of mosquitoes tested by ELISA for CSP and the number found positive for the presence of *Plasmodium falciparum* antigen are in Annex E, Table E1.

Overall, for the pre-IRS period, the mean sporozoite index (SI) was 3 percent for IRS sites (95% CI: 1.3-4.8), 0.7 percent for former IRS sites (95% CI: 0.0-2.0) and 0.8 percent for the control site (95% CI: 0.0-2.3). Post-IRS, it was 1.5 percent for IRS sites (95% CI: 0.5-2.4), and 0.8 percent for the former IRS sites and the control site (95% CI: 0.0-1.7). Although not significant (p=0.09), a reduction in mosquito infection was observed in the combined four IRS sites after the implementation of the control strategy. In former IRS sites, the sporozoite index was similar for both years at 0.8% (95%CI: 0.2-1.5) in 2017 versus 1.3% (95%CI: 0.2-2.5) in 2016; p=0.42.

N: number of An. gambiae s.l. for ELISA CSP
3.7 ENTOMOLOGICAL INOCULATION RATE (EIR)

The details on monthly variation of the EIR are provided by Annex F, Table F1.

Post-IRS, the peak of transmission was reached in all sites in September or October, except for Kati where the peak was observed in December because of the null SI recorded during the period of peak biting rate. In IRS sites, the monthly peak was 1.88, 8.1, 2.16 and 1.70 infectious bites per human per month (ib/h/month) respectively in Djénné, Mopti, Bandiagara and Bankass (Table 8). In the former IRS sites the monthly peak in September/October was 11.6 ib/h/month in Koulikoro and 16.18 ib/h/month in Barouéli. Overall, following IRS relocation, EIR in former IRS sites increased two fold to 15.37 infectious bites/human/5months in 2017 versus 7.05 ib/h/5months in 2016.

In IRS sites, the highest total EIR over the entire five month post-IRS period occurred in Mopti at 12.2 ib/h/5 months; the lowest was in Bankass (1.7 ib/h/5 months). The mean for all IRS sites post-IRS was 5.12 ib/h/5 months compared with 15.37 ib/h/5 months for the former IRS sites and 6.21 ib/h/5 months for Kati, the control site.

EIR: Entomological inoculation rate, ib/h: infected bites/human, m: months

3.8 BLOOD MEAL ORIGIN

In 2017 we changed from blood-meal ELISA to PCR (MR4) due to the large proportion of unidentified samples through ELISA and the greater specificity of PCR. However, the protocol of Kent et al (2005) did not prove specific to determine human and goat bands separately during optimization (Figure 19). Indeed, the amplification of DNA extracted directly from mosquitoes that
were fed on humans presented bands for goat. A different protocol will be used for the 2018 activities.

### 3.9 Quality of Spraying and Insecticide Decay Rate

The results of WHO cone bioassays performed 1-2 days after spraying showed mean mortality rates of 100 percent at the four different heights (Table 9). Tests during the same period for the fumigant air-borne effect of Actellic 300 CS produced mortality ranging from 96.8 percent to 100 percent according to the different type of wall encountered (Figure 20). These results indicate that IRS was conducted satisfactorily in the tested houses.

</tbody>
</table>

The monthly mortality rates obtained after cone testing per type of wall are shown in Figure 21. Mortality remained more than 80 percent for five months on painted mud and the combination of painted mud and cement, while mortality remained above 80 percent for four months on painted cement and for two months on the combination of mud (unpainted) and cement. The most frequently encountered material, mud, had a residual efficacy of 3 months. More details can be found in Annex G, Table G1.

With 30 minutes of exposure, the fumigant effect produced particularly high mortality rates up to two months after spraying, while mortality remained above 60 percent on all wall surfaces for four months after spraying, followed by a large decrease after five months (Figure 20).

3.10 VECTOR SUSCEPTIBILITY TO INSECTICIDES

Figure 22 is a series of nationwide maps showing the resistance status of Anopheles gambiae s.l. to five insecticides, based on modified WHO categories of 98 to 100 percent mortality indicating susceptibility, 91 to 97 percent mortality indicating possible resistance, 66 to 90 percent indicating resistance, 41 to 65 percent indicating high frequency resistance, and 0 to 40 indicating very high frequency resistance.

SUSCEPTIBILITY TO PIRIMIPHOS-METHYL 0.25%

In 2017, full susceptibility was observed in all sites (Table 10). More details are in Annex H, Table H1.

Figure 22: Map of *An. Gambiae* s.l. Susceptibility to 0.05% Alphacypermethrin, 0.1% Bendiocarb, 0.05% Deltamethrin, 0.75% Permethrin, And 0.25% Pirimiphos-Methyl, 2017
Susceptibility to Pyrethroid Insecticides (Permethrin 0.75%, Deltamethrin 0.05%, and Alphacypermethrin 0.05%)

Based on WHO 2013 criteria, populations of *An. gambiae* s.l. collected from all sites were resistant to all pyrethroid insecticides tested in 2017. The mean mortality rates across all sites revealed that vectors were more resistant to permethrin (0.75%) than to deltamethrin (0.05%) in 2017, as was also observed in 2015 and 2016 (Table 11). In 2017, a similar mean mortality rate was observed with permethrin (0.75%) (26%; 95%CI: 24.2-28.7) and alphacypermethrin (0.05%) (31%; 95%CI: 28.2-32.9). Overall, for permethrin 0.75%, mortality rates varied from 11% (Kadiolo) to 55% (Bankass) (Table 11) in 2017. For alphacypermethrin 0.05% and deltamethrin 0.05%, they ranged respectively from 6% in Kati to 51% in Mopti and 39% in Kita to 86% in Bandiagara (See Annex H, Table H1).

Susceptibility to Bendiocarb 0.1%

In 2017, out of the 13 sites where testing was performed, full susceptibility was noted in six sites, possible resistance in four sites and resistance in three sites—Barouéli, Sélingué and Bougouni, as shown in Table 12. More details are provided Annex H, Table H1.

%: Mortality percentage; n/a – no data available

**Susceptibility to Clothianidin 2.0% (13.2mg/paper)**

For clothianidin, mortality rates using first filial generation (F1) wild *An. gambiae* s.l. from the four IRS districts were at least 98 percent after six days (the diagnostic time recommended by Sumitomo being seven days) (see Table 13). For the negative controls, mortality rates were 6 percent or less after five days (except for Koulikoro). For the susceptible strain (Kisumu), 100 percent mortality was recorded after two days (Table 13). In Bankass and Bandiagara, mortality of wild *An. gambiae* s.l. was 96 percent five days after testing, which indicates possible resistance. However, as this is a new testing protocol, the finding of less than 100 percent mortality may also be due to test variation.

### 3.11 Insecticide Resistance Intensity Assays with Permethrin and Deltamethrin

Table 14 shows results obtained after exposing *An. gambiae* s.l. from the 15 surveyed sites to permethrin and deltamethrin at one, two, five and ten times the diagnostic dosages to assess the intensity of insecticide resistance.

Mortality rates of populations of *An. gambiae* s.l. exposed to 10 times the diagnostic dosage of permethrin ranged from 35 percent to 85 percent in all sites. After exposure to 10 times the diagnostic dosage of deltamethrin, *An. gambiae* s.l. showed a mortality rate varying from 72 percent to 97 percent. Overall, resistance to pyrethroids is quite intense at all sites with some slight differences according to insecticides and sites. The intensity of resistance was higher with permethrin than with deltamethrin. In most sites, increased mortalities are observed as the insecticide concentration increases.

3.12 Determining the Diagnostic Concentration of Chlorfenapyr in CDC Bottle Bioassays

Figure 23 displays mortality rates obtained after exposing populations of An. gambiae s.l. from four IRS sites and Kisumu strain to chlorfenapyr at concentrations of 12.5µg, 25µg, 50µg, 100µg and 200µg/bottle. At Day 3, only chlorfenapyr 100 and 200 µg/ml gave full susceptibility (defined as a mortality rate of more than 98 percent) with both field and Kisumu strains. The 100 µg/ml could be considered as the diagnostic concentration, as has been recommended by the CDC. More details are provided in Annex I, Table I1.

Figure 23: Results of An. gambiae s.l. (Field Strain and Kisumu) Tested Against Chlorphenapyr 12.5 µg/Ml, 25 µg/Ml, 50 µg/Ml, 100 µg/ml, 200 µg/ml in Djenne, Mopti, Bandiagara, and Bankass

*Not tested
In total, 750 specimens of *An. gambiae* s.l. from the 15 selected sentinel sites (50 mosquitoes/site) were tested by PCR for species identification. *An. coluzzii* was the primary vector in eleven sites, followed by *An. gambiae* in two sites (Kita and Bougouni). Both species were in similar proportion in Barouéli and Sélingué (p>0.05). Some rare specimens of *An. arabiensis* and hybrids (*coluzzii x gambiae*) were also detected (Table 15). Overall, the frequency of each species was as follows: 59.5% *An. coluzzii*, 24.7% *An. gambiae*, 2.1% *An. arabiensis* and 0.8% *An. coluzzii x gambiae* hybrids (Table 15), while 12.9% of samples did not amplify. Figure 24 displays molecular species distribution by region.

3.14 Vector Resistance Mechanisms (*kdr* 1014 F, 1014S, and *Ace1*R)

Molecular results of the 15 investigated sites are presented here. Only *An. gambiae* s.l. mosquitoes from IRS sites, former IRS sites, and sites with signs of resistance to bendiocarb and/or pirimiphos-methyl (only alive mosquitoes) were screened for the presence of *Ace1*R mutation (Table 16). Results obtained showed frequencies ranging from 0 percent in Sélingué to 53 percent in Bougouni, a site where resistance to bendiocarb was observed (76 percent mortality rate). In Bougouni, agricultural use of insecticides is practiced in high volumes. In current IRS sites of Djenné and Bandiagara, low frequency *Ace1*R resistance was detected and should be closely monitored.

For the 1014F *kdr* mutation, 588 out of 750 specimens of *An. gambiae* s.l. were amplified (details are in Table 17 & Annex J, Tables J1- J5). Combined data of the seven sites showed the mean frequency was 65 percent for *An. coluzzii* and 89 percent for *An. gambiae* (Table 17). The *kdr* 1014S mutation was absent in most sites and at very low frequency where present (Table 18).

**3.15 Mali Lab Training**

In 2016, a review of raw lab data from LBMA highlighted weaknesses with results from several protocols, in particular for sporozoite ELISA and species identification PCR. To address this several training sessions were conducted.

1) Laboratory training was held at LBMA from June 12-23, 2017. In total, 13 people participated in the training, which was led by consultants from Entomological Research Center of Cotonou (CREC), Benin.

2) Regional laboratory training was held at CREC, Benin from November 13-24, 2017 and covered all commonly used AIRS laboratory protocols. There were two participants from LBMA, Mali.

3) Follow-up practical training conducted by University of Notre Dame was held at LBMA on December 4-8, 2017. Six persons from LBMA attended this training. The focus was on specific protocols for species identification and sporozoite ELISA where specific issues were observed.

Progress made:
• LBMA now conduct laboratory testing on a monthly basis as soon as samples are received from the field. A monthly report, including the raw data (i.e., gel images for PCR and optical density values for sporozoite ELISA) is shared with Abt, University of Notre Dame, and CREC for review.

• Based on this system we have been able to quickly identify testing issues and implement solutions.

• We have high confidence in the sporozoite ELISA data for 2017. Changes in procedure include adjusting the wavelength of the plate reader, ensuring that all positive samples are repeat tested for confirmation, ensuring that the positive controls produce a value that is several times greater than the negative cut-off, and testing of 8 negative controls and 3 positive controls per plate.

• The protocol for species identification was changed and LBMA are now using the Santolamazza SINE 200 PCR method for detection of *An. arabiensis*, *An. gambiae*, and *An. coluzzii*. Previously, the proportion of hybrids detected was very high—several steps have been taken to reduce any risk of sample contamination, and hybrid rate detection in 2017 is within expected levels (less than 2%) compared with more than 30% in 2016. Any hybrids detected are repeat tested. Positive controls for all three species are now used.

• Some issues remain with blood-meal PCR which are being addressed. Refresher lab training is highly recommended for 2018 to reinforce general measures already implemented to improve the quality of PCR and ELISA data as well as follow up on any ongoing issues with blood-meal PCR or any other unusual results received in 2018.

Overall LBMA has shown a great willingness to work with partners to improve data quality and significant progress has been made for most analyzes (ELISA CSP, DNA extraction, species identification, *kdr* West/East).

### 3.16 Quality Assurance, Vector Species Identification and AceIR

Sub-samples of mosquito samples had legs removed and testing conducted on the same samples at both LBMA, Mali and Notre Dame, USA for quality assurance testing. Results have revealed there was a 91% concordance between both labs for species ID (Table 19). Overall, great progress has been made by LBMA in 2017 compared to 2016 when only 80% concordance was obtained. For the AceIR genotypes, 95% concordance was noted, which is also encouraging (Table 19).

4. Conclusions

Overall, *An. coluzzii* was the most predominant species at all sites. In IRS sites, the pre-IRS data collected in June-July 2017 revealed mean indoor *An. gambiae* s.l. density of 6.2 *An. gambiae* s.l. per house per day versus 1.8 *An. gambiae* s.l. per house per day after IRS (August-December). In Mopti, up to 11 *An. gambiae* s.l. per house per day were collected only two months after IRS operations (October). This may be due to the lower efficacy of the insecticide on walls or the fact that mosquitoes found unsprayed shelters inside houses (e.g., hanging clothes). Indeed, the results we obtained after cone bioassays revealed a residual efficacy of three months with mud, the most frequently encountered substrate. A slightly longer duration was obtained on some substrates such as painted mud, painted cement, and the combination of painted mud and cement.

The peak *An. gambiae* biting rate was obtained at all sites (except Bandiagara) in August and September 2017. The peak biting times were observed between 10:00 pm and 4:00 a.m. Overall, in IRS sites, the HBR ranged from 0.5 b/h/n in Bankass to 7.5 b/h/n in Mopti. In the former IRS sites, the large increase in *An. gambiae* s.l. biting rate in August-September 2017 compared to the same period in 2016 is of concern. The greater increase in biting rate in Koulikoro (former IRS site) compared to Kati (the paired control) indicates that IRS withdrawal may be a contributing factor. In addition, no mosquitoes were caught in 2016 by HLC in Barouéli, a former IRS site where we have a mean biting rate of 5.4 b/h/n in 2017. For both sites (Koulikoro & Barouéli), over five months (August-December), mean vector sporozoite rates in 2017 were 0.8 percent (95% CI: 0.2-1.5) and 1.3 percent (95% CI: 0.2-2.5) in 2016, but there was no significant difference (p=0.42).

The entomological inoculation rate was 7.05 ib/h/5 months for the two sites in 2016 while it was 15.37 ib/h/5 months in 2017, which equates to a two-fold increase after IRS withdrawal. A similar result was obtained in Benin by Ossé et al. (2013) following IRS relocation. Moreover, in Kati, the control site, the EIR was 18.6 ib/h/5 months in 2016 while it was 6.21 ib/h/5 months in 2017, a three-fold reduction. This supports the hypothesis that relocation of IRS contributed to an increase in the key indicators of malaria transmission.

Resistance and possible resistance to bendiocarb 0.1% were observed in several sites while full susceptibility to pirimiphos-methyl 0.25% was observed in all sites. High frequency resistance to pyrethroids in *An. gambiae* s.l. was recorded with variable levels of resistance according to the specific insecticide. With clothianidin, mortality in all four IRS sites reached at least 98 percent after six days. In Koulikoro, a former IRS site, mortality reached 100 percent after two days. Since the protocol used to test clothianidin is not yet standardized and validated by the WHO, the mortality rates of less than 98 percent that we obtained cannot necessarily be interpreted as signs of resistance. The intensity of resistance was higher to permethrin compared to deltamethrin but survivors were recorded at ten times the diagnostic dose in all sites to both pyrethroids. As previously reported, the 1014F kdr mutation was identified at high frequencies in all sites. The detection of a few homozygous resistant (RR) and heterozygous genotypes (RS) for Ace1R mutation indicates the importance of monitoring this mutation over time and raises the issue of the use of an insecticide with a mode of action different from that of carbamates and organophosphates as part of a resistance management strategy.
